#### 2.1.1 Support vector machine

The Support Vector Machine (SVM) is a binary classification algorithm, whose goal is to build the maximum margin separator between the two classes, that is the separator that maximizes the distance of the closest point from each class. The standard SVM algorithm is a linear algorithm, so in particular it will try and build the separating margin as a hyperplane in a  $d$ -dimensional space (so a  $(d - 1)$ -dimensional plane), where  $d$  is the number of features. The points that touch the margin, or that are on the wrong side of it, are called support vectors. The distance between the decision boundary and the support vectors is called margin. The algorithm will find the biggest possible margin.

Let's start assuming that the classes are linearly separable. We are provided with a dataset with  $N$   $d$ -dimensional instances  $\{\mathbf{x}_i\}_{i=0, \dots, N-1}$ . The two classes will be labelled with

$$y \in \{-1, 1\}.$$

The margin will be the the set of points

$$\{\mathbf{x} \in \mathbb{R}^d : w_0 + \mathbf{w}^T \cdot \mathbf{x} = 0\}, \quad (1)$$

for appropriate parameters  $w_0 \in \mathbb{R}$  and  $\mathbf{w} \in \mathbb{R}^d$ , which define the hyperplane and must be found by the algorithm. Now we have to find

$$\max_{w_0, \mathbf{w}}(m),$$

with the constraint

$$\frac{1}{\|\mathbf{w}\|} y_i (w_0 + \mathbf{w}^T \cdot \mathbf{x}_i) \geq m, \forall i = 0, \dots, N - 1, \quad (2)$$

that can be rewritten as

$$y_i(w_0 + \mathbf{w}^T \cdot \mathbf{x}_i) \geq m \|\mathbf{w}\|, \forall i = 0, \dots, N-1. \quad (3)$$

The constraint prevents data points from falling into the margin. Rescaling  $\mathbf{w}$  up to a multiplicative factor does not change the hyperplane it defines, so for convenience we can choose its norm such that

$$\|\mathbf{w}\| = \frac{1}{m}. \quad (4)$$

Therefore the problem becomes minimizing

$$\frac{1}{2} \|\mathbf{w}\|^2,$$

with the constraint

$$y_i(w_0 + \mathbf{w}^T \cdot \mathbf{x}_i) \geq 1, \forall i = 0, \dots, N-1. \quad (5)$$

In the theory of convex optimization one can solve for the Lagrangian dual of this problem. We can introduce the dual variables  $\alpha_i$  such that

$$\mathbf{w} = \sum_{i=0}^{N-1} \alpha_i y_i \mathbf{x}_i. \quad (6)$$

One would obtain that the dual problem consists in maximizing, with respect to the weight vector  $\alpha \in \mathbb{R}^N$ , the expression

$$f(\alpha_0, \dots, \alpha_{N-1}) = \sum_{i=0}^{N-1} \alpha_i - \frac{1}{2} \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \alpha_i \alpha_j y_i y_j (\mathbf{x}_i, \mathbf{x}_j), \quad (7)$$

with the constraint

$$\alpha_i \geq 0, \forall i = 0, \dots, N-1, \quad (8)$$

$$\sum_{i=0}^{N-1} \alpha_i y_i = 0. \quad (9)$$

In eq. (7) we indicated as  $(\mathbf{x}_i, \mathbf{x}_j)$  the standard dot product of  $\mathbb{R}^d$ , explicitly

$$(\mathbf{x}_i, \mathbf{x}_j) = \mathbf{x}_i^T \cdot \mathbf{x}_j = \sum_{k=0}^{d-1} (\mathbf{x}_i)_k (\mathbf{x}_j)_k.$$

Eq. (7) defines a quadratic programming optimization problem, therefore the global maximum of  $f$  can be efficiently found in the context of convex analysis. The parameter  $w_0$  can be found by imposing that, for a support vector

$$y_i(\mathbf{w}^T \mathbf{x}_i + w_0) = 1,$$

that is

$$w_0 = \mathbf{w}^T \mathbf{x}_i - y_i. \quad (10)$$

Once the optimal  $\alpha_i$  have been found, given a new instance  $\tilde{\mathbf{x}}$ , according to eq. (6) and eq. (1), we can predict its class calculating

$$\text{sign} \left[ \sum_{i=0}^{N-1} \alpha_i y_i (\tilde{\mathbf{x}}, \mathbf{x}_i) + w_0 \right]. \quad (11)$$

What we just described is the so called hard margin SVM, because we did not allow points to fall inside the margin. One could relax this assumption, modifying the constraint in eq. (5) into

$$y_i(w_0 + \mathbf{w}^T \cdot \mathbf{x}_i) \geq 1 - \xi_i, \forall i = 0, \dots, N-1, \quad (12)$$

where we introduced the slack variables  $\xi_i$ . We limit the softness of the margin by setting a positive constant  $C$  such that

$$\begin{aligned} \xi &\geq 0, \\ \sum_{i=0}^{N-1} \xi_i &\leq C. \end{aligned} \quad (13)$$

This is called soft margin SVM.

scikit-learn provides a straightforward implementation of the SVM algorithm, which we can use to observe the algorithm in action through an example. We use a mock dataset with 2 features, so we can easily print the data, the decision boundary and the margin.

```
from sklearn.svm import SVC
from sklearn.datasets import make_blobs
```

```
X,y = make_blobs(n_samples=100) #create mock dataset
svm = SVC(kernel='linear', C=1) #create svm
svm.fit(X, y) #fit the svm
```

The result of the fit is shown in Figure (1). We can observe how the algorithm built the largest possible margin.

Figure 1: SVM decision boundary and margin border, fitted on a 2 feature mock dataset of 100 instances.

We now need to address the issue of dealing with a highly non-linearly separable dataset. Let's consider as an example another mock dataset, shown in Figure (2). It is clear that in this case we cannot use the SVM algorithm in its basic form, not even with a soft margin. We must introduce the idea of kernelization. Let's introduce a function, called feature map, which projects the data in a higher dimensional space. That means a function

$$\phi : \mathbb{R}^d \rightarrow \mathbb{R}^D, \quad (14)$$

Figure 2: Higly non-linear 2 feature mock dataset with 100 instances.

with  $D > d$ . If we choose a suitable feature map we can hope to obtain a linearly separable dataset in the higher dimensional space. The choice of the feature map is completely arbitrary, as long as it is a bijective function. Therefore, in principle, each time we are given a dataset we must choose an appropriate feature map for this strategy to work. For our example let's consider the feature map

$$\phi : \mathbb{R}^2 \rightarrow \mathbb{R}^3,$$

$$\begin{pmatrix} x_0 \\ x_1 \end{pmatrix} \mapsto \begin{pmatrix} x_0^2 \\ x_1^2 \\ x_0^2 + x_1^2 \end{pmatrix}. \quad (15)$$

The data of Figure (2) after the application of the feature map  $\phi$  are represented in Figure (3). The dataset is now linearly separable in the higher dimensional space, so the strategy worked. We can now apply the SVM algorithm in this space Consider the two central equations of the algorithm: equation (7), which

Figure 3: Higly non-linear mock dataset after the application of the feature map  $\phi$ . We observe now that the dataset is linearly separable.

provides the expression to maximize in order to find the margin, and equation (11), which gives the rule for predicting the class of a new instance. This two equations are now modified into

$$f(\alpha_0, \dots, \alpha_{N-1}) = \sum_{i=0}^{N-1} \alpha_i - \frac{1}{2} \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \alpha_i \alpha_j y_i y_j (\phi(\mathbf{x}_i), \phi(\mathbf{x}_j)), \quad (16)$$

$$\text{sign} \left[ \sum_{i=0}^{N-1} \alpha_i y_i (\phi(\tilde{\mathbf{x}}), \phi(\mathbf{x}_i)) + w_0 \right]. \quad (17)$$

A crucial observation is that in these two expressions only the scalar product of the feature map values appears. Therefore we can conclude that the specific form of the feature map is not important, but rather the scalar product it

produces. We can define the kernel  $K$  as

$$K : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R},$$

$$(\mathbf{x}, \mathbf{y}) \mapsto (\phi(\mathbf{x}), \phi(\mathbf{y})), \quad (18)$$

where  $(\phi(\mathbf{x}), \phi(\mathbf{y})) = \phi(\mathbf{x})^T \cdot \phi(\mathbf{y})$  is the standard scalar product of  $\mathbb{R}^D$ . Eq. (16) and eq. (17) now become

$$f(\alpha_0, \dots, \alpha_{N-1}) = \sum_{i=0}^{N-1} \alpha_i - \frac{1}{2} \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \alpha_i \alpha_j y_i y_j K(\mathbf{x}_i, \mathbf{x}_j), \quad (19)$$

$$\text{sign} \left[ \sum_{i=0}^{N-1} \alpha_i y_i K(\tilde{\mathbf{x}}, \mathbf{x}_i) + w_0 \right]. \quad (20)$$

We see explicitly that the only quantity that matters is the kernel  $K$ . In our specific example the value of the kernel is
